Computational Neuroscience

An accurate skull stripping method based on simplex meshes and histogram analysis for magnetic resonance images

Francisco J. Galdames, Fabrice Jailett, Claudio A. Perez

Abstract

Skull stripping methods are designed to eliminate the non-brain tissue in magnetic resonance (MR) brain images. Removal of non-brain tissues is a fundamental step in enabling the processing of brain MR images. The aim of this study is to develop an automatic accurate skull stripping method based on deformable models and histogram analysis. A rough-segmentation step is used to find the optimal starting point for the deformation and is based on thresholds and morphological operators. Thresholds are computed using comparisons with an atlas, and modeling by Gaussians. The deformable model is based on a simplex mesh and its deformation is controlled by the image local gray levels and the information obtained on the gray level modeling of the rough-segmentation. Our Simplex Mesh and Histogram Analysis Skull Stripping (SMHASS) method was tested on the following international databases commonly used in scientific articles: BrainWeb, Internet Brain Segmentation Repository (IBSR), and Segmentation Validation Engine (SVE). A comparison was performed against three of the best skull stripping methods previously published: Brain Extraction Tool (BET), Brain Surface Extractor (BSE), and Hybrid Watershed Algorithm (HWA). Performance was measured using the Jaccard index ($J$) and Dice coefficient ($\kappa$). Our method showed the best performance and differences were statistically significant ($p < 0.05$): $J = 0.904$ and $\kappa = 0.950$ on BrainWeb; $J = 0.905$ and $\kappa = 0.950$ on IBSR; $J = 0.946$ and $\kappa = 0.972$ on SVE.

1. Introduction

Three-dimensional brain images have become increasingly popular in medical applications. These images are being used for research, diagnosis, treatment, surgical planning, and image-guided surgeries. However, several pre-processing methods are required before these images can be employed, such as image registration (Klein et al., 2010), inhomogeneity correction (Wels et al., 2011), tissue classification (de Boer et al., 2010; Wang et al., 2010), analysis of cortical structure (Thompson et al., 2001), cortical surface reconstruction (Tosun et al., 2006), cortical thickness estimation (MacDonald et al., 2000), shape quantification (Park and Seo, 2011) and/or identification of brain parts (Zhao et al., 2010).

Many of these methods achieve a brain extraction using a skull stripping process as first step, to eliminate non-brain tissue present in the image. Therefore, it is imperative to have accurate skull stripping methods available to avoid time consuming manual corrections that are not systematic and can not be applied routinely. In addition, the reliability of these processes is essential because any error at this first step will be difficult to correct in subsequent processing steps.

Many skull stripping methods have been proposed (Kapur et al., 1996; Atkins and Mackiewich, 1998; Lemieux et al., 1999, 2003; Dale et al., 1999; Ashburner and Friston, 2000; Yoon et al., 2001; Shattuck et al., 2001). Among the first commonly used methods are the Brain Extraction Tool (BET) (Smith, 2002; Jenkinson et al., 2005), Brain Surface Extractor (BSE) (Sandor and Leahy, 1997; Shattuck et al., 2001) and the Hybrid Watershed Algorithm (HWA) (Segonne et al., 2004). In BET, a mask is initially created using two thresholds estimated from the image histogram. Then, a spherical deformable model is initialized at the center of gravity of the mask. Finally, this deformable model is pushed to the brain surface by locally adaptive forces. The BSE performs brain segmentation using a sequence of anisotropic diffusion filters, Marr–Hildreth...
edge detection, and morphological processing. The HWA is a hybrid method that combines the watershed edge detection algorithm with a deformable surface model which includes shape restrictions based on a brain atlas. Another of the first commonly used methods is the 3DIntracranial (Cox, 1996; Ward, 1999). This method first models the gray levels of different tissues using Gaussian functions, and extracts upper and lower boundaries to identify brain voxels. Next, a connected component analysis is carried out slice-by-slice to identify the brain, followed by a 3D envelope process over all the slices. Finally, a neighborhood analysis is performed on each voxel to include or exclude misclassified voxels.

The above mentioned methods are commonly used for comparison, BET, BSE, ANALIZE 4.0 (Richard, 2000) and modified region growing (mRG) (Yoon et al., 2001) methods are compared in Lee et al. (2003). Boesen et al. compare their Minneapolis Consensus Strip (McStrip) (Rehm et al., 2004) method with Statistical Parametric Mapping v2 (SPM) (Ashburner and Friston, 2000), BET, and BSE in Boesen et al. (2004). A comparison among methods HWA, BET, BSE, and 3DIntracranial was carried out in Fennema-Notestine et al. (2006). More recently, a comparison study among HWA, BET and BSE was performed in Shattuck et al. (2009). Among these methods HWA has the highest sensitivity in general but the lowest specificity (Fennema-Notestine et al., 2006; Shattuck et al., 2009). HWA is prone to include unwanted subarachnoid space and non-brain tissue, particularly dura, in the segmentation. By contrast, HWA seems to be more robust to the change of parameters than other methods (Shattuck et al., 2009). There are two different indices usually used to measure the overall similarity between the gold standard and the proposed segmentation: the Jaccard index (J) (Jaccard, 1912) and the Dice coefficient (e) (Dice, 1945).

In the literature, different databases and parameters have been used in the comparisons, and therefore results vary. In Shattuck et al. (2009), the best performance was obtained by BET closely followed by BSE, and the method with worst performance was HWA. Nevertheless, BSE and HWA showed similar performance in Fennema-Notestine et al. (2006), as well as BET and 3DIntracranial, but BSE and HWA demonstrated better performance. All methods show that the sagittal sinus and the posterior fossa are the areas with the largest number of false positives.

Another example of skull stripping methods is the watershed modified algorithm proposed in Hahn and Peitgen (2000). The method presented in Grau et al. (2004) is also based on a watershed transformation that uses prior information. Elastic deformations based on atlas (Sandor and Leahy, 1997), level set methods (Baillard et al., 2001; Zhuang et al., 2006), and region growing algorithms (Park and Lee, 2009) have also been employed. In Huang et al. (2006), a hybrid method combining expectation maximization and geodesic active contours is used. A method based on an implicit deformable model which is described by radial basis functions is introduced in Liu et al. (2009). A method that uses an intensity thresholding followed by removal of narrow connections using a Bridge Burner algorithm is presented in Milheeve et al. (2008). A more recent example also using removal of narrow connections but employing a graph theoretic image segmentation technique is Sadananthan et al. (2010). A method that uses watershed segmentation, Gaussian mixture model clustering and a modification of BET is employed in Merisasari et al. (2009) to segment MRI images of premature infant brains. Techniques for combining different skull stripping algorithms to improve the segmentation have also been proposed, such as the Brain Extraction Meta-Algorithm (BEMA) (Rex et al., 2004). Recently, the multi-atlas propagation and segmentation (MAPS) method was presented in Leung et al. (2011). This method generates the brain segmentation by combining many segmentations performed by atlas registration. Another recent method which uses thresholding, length scheme, and morphological operators can be seen in Somasundaram and Kalaiselvi (2011). The Robust Learning-Based Brain Extraction (ROBEX) system is presented in Iglesias et al. (2011), which is based on a point distribution model (PDM) adjusted by using a voxel classification with the random forest algorithm. A fast level set method which uses a speedup operator is introduced in Hwang et al. (2011). The Simple Paradigm for Extra-Cerebral Tissue Removal (SPECTRE) that is based on a watershed principle and combines elastic registration, tissue segmentation, and morphological operators is described in Carass et al. (2011).

Deformable models have proven to be a robust method to segment MRI images, but they are sensitive to the initialization. In addition, simplex meshes (Delingette, 1999; Matula, 2002; Böttger et al., 2007; Tejos and Irrazaval, 2009; Gilles and Magnenat-Thalman, 2010; Galdames et al., 2011) are a simple and efficient way to implement these models and have yielded excellent results in many applications. In this paper, we report use of a simplex mesh for brain segmentation and, to avoid the initialization sensitivity problem, implementation of a rough-segmentation. This rough-segmentation ensures an optimal starting point for the deformable model. The rough-segmentation is based on histogram analysis and morphological operators, but it differs from other methods because it performs efficient comparisons with a model to guarantee a suitable result. The mesh deformation is based on the local image gray levels, and on a modeling of the tissue gray levels performed in the rough-segmentation. Therefore, local and global information is taken into account. The mesh deformation is carried out in stages, first to ensure that all the brain tissue is included, and then to refine the segmentation and remove remaining non-brain tissue. Our Simplex Mesh and Histogram Analysis Skull Stripping (SMHASS) method obtains the best performance in the most popular online databases when compared with three of the best skull stripping methods (BET, BSE and HWA). The databases used for comparison are: BrainWeb (Cocosco et al., 1997; Aubert-Broche et al., 2006), Internet Brain Segmentation Repository (IBSR) (Center for Morphometric Analysis, 1995), and Segmentation Validation Engine (SVE) (Shattuck et al., 2009). Furthermore, the method is not based on machine learning techniques (Perez et al., 2005), hence a training database is not required.

2. Methods

Most brain quantitative MRI study methods use skull stripping as a first step to eliminate non-brain tissue. The automatic method proposed in this work uses a deformable model initialized by rough-segmentation which is based on histogram analysis and is designed to eliminate most non-brain tissue.

2.1. Rough-segmentation

The rough-segmentation allows good initialization of the deformable model which is crucial step for the final segmentation. The rough-segmentation is based on thresholds, morphological operators, and modeling by Gaussian functions. It is fast, robust, and based on the fact that the brain is the largest connected structure inside the head (Shan et al., 2002; Kovacevic et al., 2002; Dogdas et al., 2005; Chiverton et al., 2007).

Usually, MRI images have non-isotropic voxel sizes; therefore, a re-sampling is first carried out using trilinear interpolation (Meijering, 2002) to obtain an isotropic image. Considering the original resolution of most of the images, we use a re-sampling resolution of 1 mm × 1 mm × 1 mm. Therefore, the values expressed in voxels or millimeters are equivalent. Nevertheless, some values are explicitly given in millimeters as they are related to the size of anatomical structures. To compute the thresholds, we consider that different tissue gray levels follow Gaussian statistics, and the...
image histogram is considered as a probability density function of the image gray levels:

\[ p(i) = \frac{n_i}{N} \]

where \( n_i \) is the number of voxels with gray level \( i \) \( = \{0, 1, 2, \ldots, \ W - 1\} \), and \( N \) is the number of voxels in the image, i.e., \( p(i) \) is the probability for a voxel to get intensity \( i \). Usually the number of gray levels may change depending on the image, but using a fixed number of bins \( W \) will allow standardizing our analysis. We used \( W = 256 \) as in Shan et al. (2002). The rough-segmentation is performed in three main steps.

### 2.1.1. Background elimination

The Otsu method (Otsu, 1979) is used, which finds the threshold, \( T_{\text{Otsu}} \), that minimizes the within-class variance between two classes. In our case, one class is formed by the very low intensity voxels corresponding to air, bone, and part of the Cerebro-Spinal Fluid (CSF) (background); and the other class is composed of the other tissues including the Gray Matter (GM) and White Matter (WM) of the brain (foreground). The within-class variance is defined as:

\[ \sigma_{\text{within}}(T_{\text{Otsu}}) = n_B(T_{\text{Otsu}})\sigma_B^2(T_{\text{Otsu}}) + n_F(T_{\text{Otsu}})\sigma_F^2(T_{\text{Otsu}}) \]

where \( \sigma_B^2(T_{\text{Otsu}}) \) and \( n_B(T_{\text{Otsu}}) \) are the variance and number of voxels in the background \( (p(i) < T_{\text{Otsu}}) \), respectively; and \( \sigma_F^2(T_{\text{Otsu}}) \) and \( n_F(T_{\text{Otsu}}) \) are the variance and number of voxels in the foreground \( (p(i) \geq T_{\text{Otsu}}) \), respectively. The original image is masked using \( T_{\text{Otsu}} \), i.e., all voxels with gray level value less than \( T_{\text{Otsu}} \) are ignored, leading to the mask, \( M_1 \), (see Fig. 1(b)) where air, bone, and most of the CSF have been removed. The removal of very low intensity voxels (background) allows focusing the processing on the tissues of interest (foreground). Next, the brain can be identified as the largest structure inside the head.

#### 2.1.2. Brain identification

The brain is first separated from other tissues by applying a threshold, \( T_s \), based on an image histogram, and a brain model mask as will be explained in this section. Then, the brain tissue is selected using morphological operators and 3D connected component analysis. The threshold for separating the brain is defined as:

\[ T_s = T_{\text{Otsu}} + \xi(\mu_{\text{gm}} - T_{\text{Otsu}}) \]

where \( \mu_{\text{gm}} \) is an estimation of the mean gray level of the GM, which corresponds to the highest value in the histogram of the image masked with \( M_1 \) (Fig. 1(b)). This definition is similar to the one proposed by Shan in Shan et al. (2002), where \( \xi \) was fixed at 0.7. We have extended this definition, leading to a more flexible threshold that can be adjusted depending on the image. \( \xi \) must be high enough to separate the brain from other tissues, while preserving the removal of brain tissue. To achieve this, the ideal \( T_s \) for each image is estimated applying thresholds computed with increasing values of \( \xi \) as follows.

Given a value of \( \xi \), the threshold \( T_s \) is computed using (3). Then, \( T_s \) is applied to the image masked with \( M_1 \) (Fig. 1(b)), and the resulting image is binarized. In this binarized image, small connections between brain and surrounding tissue may still remain. To eliminate them, a binary opening is applied 2 times to the mask, using a 3D spherical structural element with a 3 mm radius. Next, the mask, \( M_2 \) (Fig. 1(d)), is obtained by performing a 3D connected component analysis using a square connectivity equal to one, and keeping the largest element. The mask should have brain shape and therefore, to evaluate whether enough tissue has been removed, the resulting volume element is compared with the brain model mask which is a binary mask of the ICBM452 5th-order warp atlas from the Laboratory of Neuro Imaging at UCLA (Rex et al., 2003) (Fig. 1(c)). The result of this final step is a rough-segmented image (f).

**Fig. 1.** Flow diagram of the rough-segmentation method (which is divided into 3 steps). In step (I), an Otsu threshold \( T_{\text{Otsu}} \) is applied to the original image (a), to eliminate background, obtaining a masked image (b). In step (II), a threshold, \( T_s \), and morphological operators are applied to the masked image (b), obtaining a mask, \( M_2 \) (white and light gray in (d)). The threshold, \( T_s \), is adjusted by comparing the mask, \( M_2 \), with a model mask, \( M_{\text{GM}} \) (c) (Rex et al., 2003). To perform the comparison, \( M_2 \) and the model mask are registered. (d) Shows the registration: white represents \( M_{\text{CSF}} \) and \( M_{\text{GM}} \); dark gray represents only \( M_{\text{CSF}} \); and light gray represents only \( M_{\text{GM}} \). Then, if the volume, \( V_{\text{CSF}} \) (light gray in (d)) of \( M_{\text{CSF}} \) lies outside the model mask is lower than 8% of the model mask volume, \( V_{\text{GM}} \) (dark gray and white in (d)), the image masked with \( M_2 \) (e) is used in the next step (II). Otherwise, \( T_s \) is modified to eliminate more non-brain tissue. In step (III), the gray levels of different tissues are modeled using Gaussian functions. This modeling is used to compute two thresholds, \( T_{\text{CSF}} \) and \( T_{\text{GM}} \), which are used, together with morphological operators, in the image (f). The result of this final step is a rough-segmented image (f).
model mask is registered to the mask, $M_2$ before the comparison. Assuming the model mask and $M_2$ have the same orientation, a simple and direct transformation with 6 parameters is used for the registration; 3 translations and 3 scaling operations. In the coordinate axis, the transformation matches the limits of the upper part of the brain. Because usually there are tissue remnants that can cause errors when simply the “bounding box” (limits of the whole volume in the three coordinate axis) of $M_2$ is used, a careful selection of the limits is performed as follows:

The rules to find the connected volume representing the brain are designed to ensure that the head will always be recognized; hence the upper reference limit is the top of the mask in the axial direction (sagittal and coronal cuts in Fig. 2(a) and (b)). The lower reference limit is defined as the axial position, $L_{\text{bottom}}$, of the bottom of the frontal lobe (sagittal cuts in Fig. 2(a) and (b)). To identify this landmark, a set of sagittal slices in the center of the skull is analyzed, because remaining tissue may be in the lateral parts of the head (e.g., the eyes). The center of the mask bounding box is considered to be the center of the skull; and the slices at a distance from the center less than 1/30 of the bounding box’s lateral length are selected (Fig. 2(a) and (b)). The bottom of the frontal lobe is identified in a profile constructed by projecting the selected slices laterally (Fig. 2(c)). The profile is inspected in a caudal direction starting from the top of the head. At each step, the maximum value found on the profile, $v_{\text{max}}$, is updated and compared with the current value, $v_c$. We estimate that the axial position $L_{\text{bottom}}$ of the bottom of the frontal lobe is the first axial slice where the current profile value, $v_c$, has a significant difference from the current

$$v_c < v_{\text{max}} - (v_{\text{max}} - BB_{\text{min}}) \cdot 0.2$$

(4)

The anterior reference limit for the registration is $v_{\text{max}}$. The posterior reference limit is the posterior limit, $B_{\text{post}}$, of the projection of the central slices at the slice where $v_{\text{max}}$ was found (Fig. 2(c)). The lateral reference limits are the bounding box lateral limits of the upper part of the mask, from the top of the head to the bottom of the frontal lobe, $L_{\text{bottom}}$ (axial cuts in Fig. 2(a) and (b)).

After registration, $M_2$ is compared to the model mask (see Fig. 1(d)) to check whether the non-brain tissue has been properly removed. If the volume (number of voxels) of $M_2$ lying outside the model mask, $V_{\text{out}}$ (light gray in Fig. 3), is small enough compared to the volume of the model mask, $V_M$ (dark gray and white in Fig. 3), it is assumed that the tissue removal is successful. Therefore, an empirical threshold of 0.08 is used, and the following condition should be satisfied to accept the tissue removal:

$$\frac{V_{\text{out}}}{V_M} < 0.08$$

(5)

Eq. (5) determines whether enough non-brain tissue has been removed to proceed with the histogram analysis. The volume of mask $M_2$ that lies outside the model after registration, $V_{\text{out}}$, is an estimate of the non-brain tissue. When $V_{\text{out}}$ is large compared to the model’s volume $V_M$, a significant part of non-brain tissue is present in the mask $M_2$. Fig. 3 shows an example in which the volume $V_{\text{out}}$ is large because the mask $M_2$ includes non-brain tissue. This non-brain tissue must be removed before performing the next step of our method. To remove the tissue, the threshold $T_s$ is increased in Eq. (3) by using a higher value of $\xi$ in the set $\xi = \{0.1, 0.2, ..., 0.9\}$. If (5) is satisfied, no more values of $\xi$ are tested and the current mask $M_2$ is used in the next step of the rough-segmentation (Fig. 1(e)). The first value of $T_s$ is lowest to avoid removing brain tissue. Moreover, if some brain tissue is removed in this step, it is recovered in the second deformation of the mesh as is explained in Section 2.2.3.3.

After the procedure described above, some parts of other tissues, such as dura, still remain around the brain. Thus, other thresholds are required, and they are computed by assuming that those tissues belong to a class depending on their gray levels. The classes are modeled by Gaussian functions, and the resulting model is used to compute the new thresholds (Section 2.1.3) and as part of the information to guide the deformable model (Section 2.2).

![Fig. 2](Image 89x182 to 310x475)

References used to register (a) the Rough-segmentation Mask $M_2$, and (b) the Model Mask. This registration is used to estimate the value of $\xi$ in the computation of threshold, $T_s$. The limits used to compute the registration are marked with red boxes. The bottom of the frontal lobe, $L_{\text{bottom}}$, is used as the caudal limit, which is found using the central sagittal slices marked in coronal and axial cuts ((a) and (b)). A frontal profile (c) of the lateral projection of the central slices is used to identify the bottom of the frontal lobe, the first axial slice where $v_c < v_{\text{max}} - (v_{\text{max}} - BB_{\text{min}}) \cdot 0.2$. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

![Fig. 3](Image 402x687 to 536x784)

Example of non-brain tissue in mask $M_2$. A large volume of $M_2$ lies outside the model. This volume $V_{\text{out}}$ is represented in light gray and corresponds to non-brain tissue that must be removed. In this case, Eq. (5) is not satisfied, therefore the threshold $T_s$ must be increased by using a higher value of $\xi$ in Eq. (3).
2.1.3. Histogram modeling by Gaussians

Elimination of non-brain tissue is performed in this stage by the application of thresholds computed using a Gaussian approximation of the image histogram. The brain tissue is also selected using morphological operators and 3D connected component analysis of the image histogram. The class correspond to main function modes. In order to localize the modes of the function, the parameter, \( h \), is adjusted to obtain a smooth function whose number of peaks is equal to the number of modes we want to identify. The larger the value of \( h \), the smoother the estimation \( \hat{p}(i; h) \) and the fewer the number of local maxima. The adjustment of \( h \) to obtain a desired number of local maxima, \( m \), is explained as follows.

First, two limit values for \( h \) are fixed: \( h_{\text{high}} \) and \( h_{\text{low}} \). Since \( m \) modes should be found, \( h_{\text{high}} \) must be high enough to obtain \( m < m \) modes when it is used in the estimation, and \( h_{\text{low}} \) must be low enough to obtain \( m > m \) modes. Then, \( h \) is adjusted iteratively, providing a value, \( h_t \) at each iteration, \( t \), starting with \( h_0 = (\text{max} \ast \text{min})/2 \):

1. Compute \( \hat{p}(\cdot; h_t) \) (Eq. (8)).
2. Compute the number of modes \( \hat{m} \) in \( \hat{p}(\cdot; h_t) \).
3. If \( \hat{m} \leq m \) then
   - \( h_{\text{high}} = h_t \)
   - \( h_{\text{low}} = h_t \)
   end if
4. Compute \( h_{t+1} = h_{t} - (h_{t} - h_{t-1})/1000 \).
5. If \( \hat{m} = m \) and \( |h_t - h_{t+1}| < 0.001 \) then
   return \( \hat{p}(\cdot; h_{t+1}) \)
else
   go to step 1.
end if

The class \( C_1 \) does not always show a peak. Therefore, to compute the initial vector of parameters to adjust \( p^*(\cdot; v) \), the best method is to find the peaks of classes \( C_2 \) and \( C_3 \). Because \( \mu_2 \) and \( \mu_3 \) are the highest peaks in the histogram, they can be located using the algorithm described above. Using these estimations of the mean gray levels, the initial vector of parameters \( v = (\mu_k, \sigma_k, p_k) \) for the adjustment of the Gaussian functions (Eq. (7)) is obtained: \( v = [\mu_2, \mu_3, W/6, \mu_2, \mu_3, W/6, \mu_2, \mu_3, W/6, \mu_2, \mu_3, W/6, \mu_2, \mu_3] \). This initial vector is used in the Levenberg–Marquardt algorithm to perform the minimization of Eq. (7), and obtain the optimal vector of parameters \( v^* \) for the approximated histogram, \( p^*(\cdot; v) \) (Eq. (6)). Fig. 4 shows the image histogram, \( p(i) \) (black dashed line), and the approximated histogram, \( p^*(\cdot; v) \) (solid red line) formed by the sum of the Gaussian functions representing the gray level distributions of classes \( C_1 \) (green line), \( C_2 \) (yellow line), and \( C_3 \) (blue line). Because

\[
p'(i; v) = \sum_{k=1}^{3} p_k \exp \left( -\frac{1}{2} \left( \frac{i - \mu_k}{\sigma_k} \right)^2 \right)
\]

where \( W \) is the number of gray levels or bins in the histogram. This minimization is performed using the Levenberg–Marquardt algorithm (Moré, 1978), which is especially suitable for minimizing functions that can be expressed as a sum of squared residuals. The initial vector of parameters for the minimization is computed using a non-parametric smoothing method. This method is based on kernel density estimation (Rosenblatt, 1956) which is a technique used to estimate the probability density function of a random variable. In our case, this variable is the image histogram, \( p(i) \). Thus, the kernel density estimation is:

\[
\hat{p}(i; h) = \frac{1}{NH} \sum_{j=0}^{W-1} p(j) K \left( \frac{i - j}{h} \right)
\]

where \( K \) is the kernel function, \( h \) is the bandwidth parameter of the kernel (Eq. (9)), and \( j \) is the internal variable of the summation over all the \( W \) gray levels. The commonly used normal distribution with mean 0 and variance 1 is used as the kernel function:

\[
K \left( \frac{i - j}{h} \right) = \frac{1}{\sqrt{2\pi} h} e^{-\left(\frac{i - j}{2h}\right)^2}
\]

In this way, the variance is controlled indirectly through parameter \( h \). This parameter controls the amount of smoothing of \( \hat{p}(i; h) \), i.e., when \( h \) is high, \( \hat{p}(i; h) \) will be smoother. Since the image histogram is seen as a probability density function, the peaks of each class correspond to main function modes. In order to localize the modes of the function, the parameter, \( h \), is adjusted to obtain a smooth function whose number of peaks is equal to the number of modes we want to identify. The larger the value of \( h \), the smoother the estimation \( \hat{p}(i; h) \) and the fewer the number of local maxima. The adjustment of \( h \) to obtain a desired number of local maxima, \( m \), is explained as follows.

First, two limit values for \( h \) are fixed: \( h_{\text{high}} \) and \( h_{\text{low}} \). Since \( m \) modes should be found, \( h_{\text{high}} \) must be high enough to obtain \( m < m \) modes when it is used in the estimation, and \( h_{\text{low}} \) must be low enough to obtain \( m > m \) modes. Then, \( h \) is adjusted iteratively, providing a value, \( h_t \) at each iteration, starting with \( h_0 = h_{\text{high}} + h_{\text{low}}/2 \):

1. Compute \( \hat{p}(\cdot; h_t) \) (Eq. (8)).
2. Compute the number of modes \( \hat{m} \) in \( \hat{p}(\cdot; h_t) \).
3. If \( \hat{m} \leq m \) then
   - \( h_{\text{high}} = h_t \)
   - \( h_{\text{low}} = h_t \)
   end if
4. Compute \( h_{t+1} = h_t - (h_t - h_{t-1})/1000 \).
5. If \( \hat{m} = m \) and \( |h_t - h_{t+1}| < 0.001 \) then
   return \( \hat{p}(\cdot; h_{t+1}) \)
else
   go to step 1.
end if

The class \( C_1 \) does not always show a peak. Therefore, to compute the initial vector of parameters to adjust \( p'(\cdot; v) \), the best method is to find the peaks of classes \( C_2 \) and \( C_3 \). Because \( \mu_2 \) and \( \mu_3 \) are the highest peaks in the histogram, they can be located using the algorithm described above. Using these estimations of the mean gray levels, the initial vector of parameters \( v = (\mu_k, \sigma_k, p_k) \) for the adjustment of the Gaussian functions (Eq. (7)) is obtained: \( v = [\mu_2, \mu_3, W/6, \mu_2, \mu_3, W/6, \mu_2, \mu_3, W/6, \mu_2, \mu_3] \). This initial vector is used in the Levenberg–Marquardt algorithm to perform the minimization of Eq. (7), and obtain the optimal vector of parameters \( v^* \) for the approximated histogram, \( p^*(\cdot; v) \) (Eq. (6)). Fig. 4 shows the image histogram, \( p(i) \) (black dashed line), and the approximated histogram, \( p^*(\cdot; v) \) (solid red line) formed by the sum of the Gaussian functions representing the gray level distributions of classes \( C_1 \) (green line), \( C_2 \) (yellow line), and \( C_3 \) (blue line). Because
class $C_2$ represents the gray matter and class $C_3$ the white matter, it can be assumed that the mean value and standard deviation of the GM and WM gray level are, $\mu_{gm} = \mu_2$, $\sigma_{gm} = \sigma_2$, and $\mu_{wm} = \mu_3$, $\sigma_{wm} = \sigma_3$, respectively.

Two final thresholds, $T_{\text{GLow}}$ and $T_{\text{GHigh}}$, are computed using the estimated gray level distribution of the tissues (Shan et al., 2002):

$$T_{\text{GLow}} = \mu_{gm} - 2.5\sigma_{gm} \quad T_{\text{GHigh}} = \mu_{wm} + 2.5\sigma_{wm}$$

A new mask is computed using these thresholds (Fig. 1(f)). The mask is composed of all voxels, in the image masked with $M_2$, having a gray level, $i$, that satisfies: $T_{\text{GLow}} \leq i \leq T_{\text{GHigh}}$. With the purpose of disconnecting the remaining tissues with gray levels similar to the brain, a binary opening is used in the mask. The opening operator is applied once, using a 3D spherical structural element with a radius of 5 mm. Then, to identify the brain, a 3D connected component analysis is performed in the mask, using a square connectivity equal to one. The largest element is kept, and it forms the mask, $M_3$. The original image masked by $M_3$ is the final rough-segmentation of the brain. Fig. 5 shows two orthogonal slices of the MRI rough-segmentation, in which tissues have been eliminated, except for the cerebral parenchyma (Fig. 5(c)).

2.2. Segmentation by deformable models

The final segmentation is carried out by deformable models, using the original and the rough-segmented images. The deformable model is based on a simplex mesh. A detailed description of simplex meshes is given by Delingette in Delingette (1999), where it is reported that simplex mesh properties make them suitable for a wide range of segmentation tasks. In our segmentation, a generic mesh, $M$, is deformed to reach the GM-CSF interface. First, this generic mesh is geometrically adjusted using an affine transformation computed by identification of landmarks in the rough-segmented image. Next, the mesh is deformed using the rough-segmented image, and then by using the original image. The deformation of the model is carried out following three steps.

2.2.1. Initial mesh generation

The ICBM452 5th-order warp atlas (Rex et al., 2003) (Laboratory of Neuro Imaging (LONI) at UCLA) was used to build the generic mesh, $M$. This atlas represents an average of the intensities and anatomical shapes of T1-weighted MRI images of normal young adult brains. A mesh with genus 0 was built using the well known marching cubes algorithm (Lorensen and Cline, 1987) on the ICBM452 atlas. The result of the marching cubes algorithm is a triangulation; however, a triangulation can be transformed into a simplex mesh by applying a dual operation (Galdames and Jaillet, 2010) (see Fig. 7(c)). The generic mesh does not include the sulci or gyri in details; but these structures are incorporated during the mesh deformation. The geometric adjustment of the generic mesh to the rough-segmentation volume is explained in the next section.

2.2.2. Mesh geometric adjustment

After rough-segmentation, a global matching of the generic mesh, $M$, is carried out using geometric transformations. First, $M$ is scaled and translated to match the rough-segmented MRI. The references used to carry out this transformation are found in the same way as the estimation of threshold $T_s$ that is described in Section 2.1.2. The caudal limit of the frontal lobe and the bounding box of the upper part of the brain in $M$ are matched with the same references in the rough-segmented image.

Next, an affine transformation is carried out minimizing the sum of the square distances among the mesh vertices and the rough-segmented MRI edges. The optimal transformation parameters are found using the Levenberg–Marquardt minimization method. The distances in the rough-segmented MRI image are pre-computed using the distance transformation on the edges of the MRI segmentation after binarization. Fig. 6(a) shows the cortex mesh after the affine transformation.

2.2.3. Simplex meshes applied to brain segmentation

In this section, simplex meshes are introduced, and the theory for their deformation is explained in relation to brain segmentation. The model is deformed using information from both rough-segmented and original images to discriminate between GM and CSF in order to find the interface between them. The deformation is directed by local forces computed over the gray levels of the image.

2.2.3.1. Simplex meshes. A general description of simplex meshes is presented here. A $k$-simplex is the convex hull of $k + 1$ independent points, e.g., a segment is a 1-simplex, a triangle is a 2-simplex, and a tetrahedron is a 3-simplex. By definition, a $k$-simplex mesh has a $k + 1$-simplex in each vertex. For example, a 1-simplex mesh is a contour in which each vertex and its two neighbors define a triangle. This property defines the connectivity of the mesh where the vertices of a $k$-simplex mesh have $k + 1$ neighbors. The types of objects that can be represented by these meshes depends on the mesh connectivity, e.g., a $k$-simplex mesh with $k = 1$ can represent a curve, $k = 2$ a surface, and $k = 3$ a volume. To segment the brain surface, we use 2-simplex meshes. Each vertex of these meshes has three neighbors, and these four points define a tetrahedron (Fig. 7(a)); $P_i, P_{N1(i)}, P_{N2(i)}, P_{N3(i)}$. An interesting feature of 2-simplex meshes is that they are the topological dual of the triangulations (meshes of triangles); making it possible to obtain a 2-simplex mesh by applying a dual operation to a triangulation, and vice versa (Fig. 7(c)). This property is useful because it is more convenient to

---

Fig. 6. Examples of deformation steps with the simplex mesh: (a) after geometric adjustment by affine transformations (Section 2.2.2). (b) After a first deformation to match the rough-segmentation (Section 2.2.3.2). (c) After a second deformation to roughly match the cortex surface (Section 2.2.3.3). (d) After a refined third deformation to match the sulci and gyri (Section 2.2.3.4). (e) Zoom image of the final deformation that shows the mesh following the sulci and gyri.

represent a surface with a triangulation for some tasks, e.g., rendering, computing intersections, or constructing volumetric meshes. Hereafter, we will refer to 2-simplex meshes simply as simplex meshes.

As mentioned, each vertex of a simplex mesh positioned at $P_i$ has three neighbors, positioned at $P_{N(i)}$, $P_{N2(i)}$, $P_{N3(i)}$. The vertex and its neighbors form a tetrahedron (see Fig. 7(a)). It is possible to compute the tetrahedron’s circumscribed sphere with center, $O_i$, and radius, $R_i$, defined by these four points, and the circle with center $C_i$ and radius $r_i$, defined by the three neighbors. The three neighbors also define a plane with normal $N_i$, which includes the circle with center $C_i$. With these geometric entities, the simplex angle $\rho_i \in [-\pi, \pi]$ can be defined (see Fig. 7(b)):

$$\sin(\rho_i) = \frac{r_i}{R_i} \text{sgn} \left( \vec{P}_i \vec{P}_{N(i)} \cdot \vec{N_i} \right)$$ or $$\cos(\rho_i) = \frac{||\vec{O}_i \vec{C}_i||}{R_i} \text{sgn} \left( \vec{O}_i \vec{C}_i \cdot \vec{N}_i \right)$$ (11)

where sgn is the sign function and $\langle \rangle$ is the inner product. Therefore, the simplex angle $\rho_i$ is defined in every vertex $P_i$ by means of its neighbors $P_{N(i)}$, $P_{N2(i)}$, $P_{N3(i)}$, and it does not depend on the position of the neighbors within the circle they define. The simplex angle and the height $L$ (Fig. 7(a)) of $P_i$ over the plane defined by its neighbors are related by:

$$L(r_i, d_i, \rho_i) = \frac{(r_i^2 - d_i^2) \tan(\rho_i)}{\chi \sqrt{r_i^2 + (r_i^2 - d_i^2) \tan^2(\rho_i) + r_i^3}}$$

$$\chi = \begin{cases} 1 & \text{if } |\rho_i| < \pi/2 \\ -1 & \text{if } |\rho_i| > \pi/2 \end{cases}$$ (12)

where $d_i = ||\vec{C}_i \vec{P}_i \perp||$, and $P_i \perp$ is the projection of $P_i$ over the plane defined by its neighbors. Since the simplex angle is scale-invariant, it can be seen as a local and scale-invariant measure of the height, $L$, of $P_i$ over the plane defined by its neighbors. Moreover, the simplex angle is related to the surface curvature at $P_i$. It is possible to approximate the curvature at $P_i$ by the curvature of the sphere that best fits the surface in a neighborhood around $P_i$. If the neighbors $P_{N(i)}$, $P_{N2(i)}$, $P_{N3(i)}$ of $P_i$ are considered, this sphere is the circumscribed sphere of the tetrahedron formed by the four points (Fig. 7(a)), and its mean curvature is $H_i = 1/R_i$. This mean curvature at point $P_i$ can be expressed in terms of the simplex angle (Delingette, 1999) using (11): $H_i = \sin(\rho_i)/r_i$. Other important geometric entities of the simplex meshes are the metric parameters $\varepsilon_{1i}, \varepsilon_{2i}, \varepsilon_{3i}$. These parameters are the barycentric coordinates of the projection, $P_i \perp$, of the vertex, $P_i$, on the triangle defined by its neighbors (Fig. 7(a)):

$$P_i \perp = \varepsilon_{1i} P_{N(i)} + \varepsilon_{2i} P_{N2(i)} + \varepsilon_{3i} P_{N3(i)}$$

$$\varepsilon_{1i} + \varepsilon_{2i} + \varepsilon_{3i} = 1$$ (13)

The position of a vertex projection on the plane defined by its neighbors is defined by (13), and the height of the vertex over this plane.
by (12). Therefore, the metric parameters and the simplex angle completely determine the position of the vertex as follows:

\[ P_i = \varepsilon_1 P_{N1(i)} + \varepsilon_2 P_{N2(i)} + \varepsilon_3 P_{N3(i)} + L(\rho_i, d_i, \rho_i') \vec{N}_i \]  

(14)

The simplex mesh deformation can be controlled by internal and external forces. The external forces are computed from the image, and push the mesh to the desired borders. The internal forces are computed from the mesh, considering a smooth deformation and keeping the mesh regularity.

Now, we describe how the mesh can be deformed. The dynamics of the model are controlled by means of a Newtonian law of motion:

\[ m \frac{d^2 P_i}{dt^2} = -\gamma \frac{dP_i}{dt} + \lambda F_{\text{int}}^i + vF_{\text{ext}}^i, \]  

(15)

where \( m \) is the mass of the unit of a vertex (usually 1; Delingette, 1999), \( \gamma \) is a damping factor, \( P_i \) is the position of vertex \( i \), \( F_{\text{int}}^i \) represents the internal force at vertex \( i \), \( F_{\text{ext}}^i \) represents the external force, \( \lambda \) is a weight for the internal force, and \( v \) is a weight for the external force. The weights \( \lambda \) and \( v \) control the influence of each force on the deformation. Considering discrete time and using finite differences in Eq. (15), we obtain:

\[ P_i^{t+1} = P_i^t + (1 - \gamma) \left( P_i^t - P_i^{t-1} \right) + \lambda F_{\text{int}}^i + vF_{\text{ext}}^i \]  

(16)

The internal force of a simplex mesh can be locally determined by the simplex angle, \( \rho_i \) and the metric parameters \( \varepsilon_{1i}, \varepsilon_{2i}, \varepsilon_{3i} \). The internal force is a spring force between the position of the vertex \( P_i \) and a target position \( P_i^* \) computed at each iteration in a neighborhood around the vertex \( i \). A set of sampling points is defined over each vertex profile (see (18)). To compute the target point, \( P_i^* \) can be fixed in a value or computed at each iteration in a neighborhood around the vertex to obtain a curvature continuity constraint (Delingette, 1999). We perform different mesh deformations, and in each one, a different definition of the external force \( F_{\text{ext}}^i \) and \( \rho_i^* \) is used. In each deformation, (16) is iterated until the mean displacement of the mesh vertices is less than 0.01. These deformations are explained in the following sections.

2.2.3.1. First mesh deformation. After the geometric adjustment (Section 2.2.2), the mesh, \( \mathcal{M} \), is deformed in order to match the rough-segmentation borders more accurately. In (15), the external force definition is important as it allows driving the mesh to the image’s natural edges. Its computation is achieved by using the normal profile to each vertex, in a way similar to Active Shape Models (Cooper et al., 1995; Weese et al., 2002). However, as reported in this paper, an elastically deformable model is used, avoiding the need for a training set. A set of sampling points is defined over each normal profile of length 2\( l \) as:

\[ x_{i,j} = P_i + j\delta \vec{N}_i \]  

(18)

where \( \delta \) is a sampling distance, and \( j = \{-l/\delta, \ldots [-l/\delta] + 1, \ldots, [l/\delta] - 1, [l/\delta]\} \). Fig. 8 shows the normal profiles for a specific mesh. A target point, \( x_i^\text{target} \), defined as the first point inside the mask, \( M_3 \), is searched in each profile, starting from \( l \) to \(-l \). Thus, using the target point, the external force, \( F_{\text{ext}}^i \), is defined in each vertex as:

\[ F_{\text{ext}}^i = \frac{\nabla M_3(x_i^\text{target})}{|\nabla M_3(x_i^\text{target})|} \cdot (x_i^\text{target} - P_i) \vec{N}_i \]  

(19)

where \( \nabla M_3(x_i^\text{target}) \) is the gradient of \( M_3 \) at \( x_i^\text{target} \), i.e., the gradient of the mask border. In this way, the vertex is pushed to the rough-segmentation border more strongly if the normal of the mask border is in the same direction as the mesh normal.

Because an affine transformation was used in the previous mesh geometric adjustment, it can be assumed that the mesh did not lose its general shape. Therefore, to avoid an excessive mesh deformation if there are errors in the rough-segmentation, the initial simplex angles of the mesh are preserved as target simplex angles, \( \rho_i^* \) during the deformation. Thus, the simplex angle of every vertex, \( \rho_i \), is computed after the geometric adjustment and used in this deformation as \( \rho_i^* \) (Eq. 17). An example of the adjustment result to the rough-segmentation is shown in Fig. 6(b).

After this first deformation, the mesh matches the rough-segmented image borders. Because the rough-segmentation is designed to remove most of the non-brain tissue, the mesh lies mainly in the WM or near the GM-CSF interface.

2.2.3.2. Second mesh deformation. The second deformation is computed using the original MRI, and the goals are to find the GM-CSF interface, and correct the mesh in those areas where the rough-segmentation eliminated brain tissue. Therefore, the mesh moves mainly inside the WM or near the GM-CSF interface in this deformation.

In a similar manner to the first deformation, a target point, \( x_i^\text{target} \), is computed in each vertex profile (see (18)). To compute the target point, rules based on the image gray level are applied, as will be explained later in this section (Fig. 9). In each iteration, the vertices are pushed toward their target points by the external force. To accomplish this, the external force, \( F_{\text{ext}}^i \), is computed using the

\[ x_i^\text{target} \rightarrow \text{eq. (25)} \]  

\[ x_i^\text{target} \rightarrow \text{eq. (26)} \]  

\[ x_i^\text{target} \rightarrow \text{eq. (28)} \]
target points and including an exponential decay if the target point is further than a distance, $D_F$:

$$F_{\text{ext}} = (x_i^\text{target} - P_i)\beta$$

where

$$\beta = \begin{cases} 
1, & \text{if } \|x_i^\text{target} - P_i\| < D_F \\
\exp\left(\|x_i^\text{target} - P_i\| - D_F\right), & \text{if } \|x_i^\text{target} - P_i\| \geq D_F 
\end{cases}$$

Fig. 9 shows a flow diagram of the rules employed to compute the target points. First, whether the vertex $P_i$ is outside the WM is estimated. This is carried out by computing two values: an estimation of the WM gray value in each profile

$$I_{\text{wm}}(i) = \max_{j=-\|\delta_i\|,...,0} I(x_{ij}),$$

and the minimum gray level value over a distance, $d_{\text{min}}$ in the direction, $-\vec{N}_i$:

$$I_{\text{min}}(i) = \min_{j=-d_{\text{min}}/\|\delta_i\|,...,0} I(x_{ij})$$

If $I_{\text{min}}(i) \leq 0.66 I_{\text{wm}}(i)$, it is assumed that the vertex, $P_i$, is inside the CSF or the GM. In this case, another measurement is made over a distance, $d_{\text{mean}}$ in the direction, $-\vec{N}_i$:

$$I_{\text{mean}}(i) = \frac{\sum_{j=-d_{\text{mean}}/\|\delta_i\|}^{0} I(x_{ij})}{d_{\text{mean}}/\|\delta_i\| + 1}$$

Using $I_{\text{mean}}(i)$, it is possible to determine whether the vertex, $i$, is near the GM. If $I_{\text{mean}}(i)$ has a low value, the vertex, $i$, is in the CSF far from the GM. In this case, $P_i$ must be pushed to reach the GM. $I_{\text{mean}}(i)$ is analyzed using the mean value $\mu gm$ and standard deviation $\sigma gm$ of the GM gray level computed in Section 2.1.3. Accordingly, if $I_{\text{mean}}(i) < \mu gm - 8\sigma gm$, the vertex is pushed inward. Since each vertex is pushed over its target point, the target point is defined as:

$$x_i^\text{target} = P_i - d_p \vec{N}_i$$

where $d_p$ is a distance that controls the applied force. Otherwise, if $I_{\text{mean}}(i) \geq \mu gm - 8\sigma gm$, it is assumed that the vertex is near the interface between the GM and CSF, and must be pushed into it. This interface can be detected looking for a high gradient in the search profile. A function, $\mathcal{F}$, based on both image and mesh, is defined as $\mathcal{F}_i(x) = -\vec{N}_i \cdot \nabla I(x)$, where $I(x)$ is the gray value of the image normalized between the values $[0,1]$ at point $x$, and $\nabla$ is the gradient operator. Then, the target point (Weese et al., 2002) is defined as:

$$x_i^\text{target} = P_i + D \arg\max_{j=-\|\delta_i\|,...,0} [\mathcal{F}_i(x_{ij}) - D^2 \|\delta_i\|^2 \vec{N}_i]$$

where $D$ is a weight to give less importance to points that are far from $P_i$. In contrast, if $I_{\text{max}}(i) > 0.66 I_{\text{wm}}(i)$, it is assumed that the vertex $P_i$ is inside the WM. In this case, another measure is performed over a distance, $d_{\text{max}}$, in the profile:

$$I_{\text{max}}(i) = \max_{j=0,...,d_{\text{max}}/\|\delta_i\|} I(x_{ij})$$

The purpose of $I_{\text{max}}(i)$ is to determine whether the eyes are in front of $P(i)$. An area with high gray level values characterizes the region behind the eyes, where the optic tracts are located. We estimated a threshold for $I_{\text{max}}(i)$ to be 130% of the WM intensity. If $I_{\text{max}}(i) > 1.3 I_{\text{wm}}$, it is assumed that the eyes are in front of $P_i$, and the GM border is found using (26); otherwise, the vertex $P_i$ inside the WM and must be pushed to reach the GM and the GM-CSF interface. The vertex is pushed defining the target point $x_i^\text{target}$ as:

$$x_i^\text{target} = P_i + d_p \vec{N}_i$$

In the second deformation, the mesh should be adjusted more precisely. Therefore, it is allowed more freedom in the deformation by defining the target simplex angle, $\rho_i$, using a curvature continuity constraint (Delpingette, 1999) computed over a neighborhood, $Q^2(i)$, of size, $S$, around each vertex. The neighborhood, $Q^2(i)$, is defined as all the vertices that can be connected to $P_i$ by a path formed with $S$ edges. Fig. 6(c) shows an example of the mesh obtained after the second deformation.

The rough-segmentation is designed to eliminate the non-brain tissue to be able to find landmarks to register the generic mesh, $M$, with the image (Section 2.2.2), but in some cases part of the brain is also removed. Therefore, the purpose of the second deformation, in addition to reaching the GM-CSF interface, is to correct the mesh in those areas where the rough-segmentation eliminated brain tissue. Fig. 10 shows an example in which part of the brain was removed in the rough-segmentation and recovered in the second deformation.

2.2.3.4. Third mesh deformation. A final deformation is carried out removing parts of the CSF that may remain outside the cortex or in the sulci, by mesh refinement, and using similar forces to those described in the previous section. There are many well-known algorithms to refine triangulations. Therefore, the simplex mesh is first transformed into a triangulation using the method described in Galdames and Jailet (2010). This method is based on the computation of the dual mesh vertices by an interpolation that uses a direct minimization of the distance to both vertices of each face and the tangent planes in these vertices. After the dual transformation, the triangulation is refined using the butterfly scheme (Zorin et al., 1996), and re-transformed into a simplex mesh (Galdames...
and Jaillet, 2010). To deform the refined mesh, similar forces to those described in the previous section (Section 2.2.3.3) are utilized. The difference is that the value of $l_{\text{wm}}(i)$ is modified if it is very different from the estimation of the WM gray level in the rough-segmentation stage. The objective of this correction is to make sure that vertices over sulci will be pushed into the sulci. There are cases in which the estimation of the WM local gray level $l_{\text{wm}}(i)$ is excessively low when the vertex is over a large sulcus, especially over the sagittal sinus. Moreover, in this stage the mesh has reached the cortex as a result of the second deformation; therefore, it is more important to push the vertices into the sulcus. If $l_{\text{wm}}(i) < \mu_{\text{wm}} - 2\sigma_{\text{wm}}$, its value is replaced by $l_{\text{wm}}(i) = \mu_{\text{wm}} - 2\sigma_{\text{wm}}$.

Fig. 6(d) shows an example of the final segmentation.

2.2.3.5. Mesh self-intersections control. Mesh deformations following complex shapes such as cortex sulci and gyri, may generate errors due to mesh self-intersections. A self-intersection may cause the surface normal vector to point toward inside the mesh instead of outward. This error in the normal vector causes the mesh to be pushed in the wrong direction, because the forces that deform the mesh depend on the surface normal vector. The mesh internal forces avoid these intersections to some degree, but in some cases they are not sufficient.

To prevent these self-intersections, their occurrence is checked and corrected every $T = 10$ iterations. The vertices that form a face of a simplex mesh are not co-planar; therefore, there are no planes available to compute the intersections easily. Consequently, the simplex mesh is first transformed into its dual triangulation (Galdames and Jaillet, 2010) to have a mesh formed by planar faces. Then, the intersections between triangles can be computed easily. Because the topological dual triangulation is used, each triangle corresponds to a vertex of the simplex mesh (Fig. 7(c)). Therefore, if an intersection is detected in a triangle, the position of the corresponding simplex mesh vertex must be corrected. After all triangles with intersections have been detected, areas enclosed by these triangles are computed. The triangles of these areas have completely crossed a part of the mesh. Therefore, the position of the simplex mesh vertices related to triangles in the enclosed areas must also be corrected.

Consequently a set, $G$, is formed with the vertices related to intersected triangles and triangles enclosed by intersections. To correct the intersections, a Laplacian smoothing is applied to the vertices of $G$ and to a neighborhood around them. The smoothing is applied in stages $k = \{1, 2, \ldots\}$ to make sure of the self-intersection problem correction, while changing the rest of the mesh as little as possible. In each stage, the Laplacian smoothing is applied 50 times or until the mean displacement of the vertices is less than 0.001.

Another detection of self-intersections and enclosed areas is performed at the end of each stage. If there are still self-intersections, another set, $G$, is formed in the next stage and a Laplacian smoothing is carried out. The neighborhood around $G$ depends on the stage, $k$, defining increasing neighborhoods to provide more freedom if the intersections were not corrected in the previous stage. Thus, in a stage $k$, the neighborhood $Q^k(G)$ of $G$ is of size $S = k$, where $Q^0(G)$ is defined as all the vertices that can be connected to any vertex of $G$ by a path formed with $S$ edges.

2.2.3.6. Conditional morphological operators. The purpose of the skull stripping method is to classify voxels in the image as brain or non-brain tissue. After the mesh deformation, a binary mask is built using the final mesh. Voxels inside the mesh are classified as brain tissue and as non-brain tissue those voxels outside the mesh. Because the mesh has no sub-voxel resolution to perform an efficient deformation, some voxels in the surface of the mask can be misclassified. To refine the classification of these voxels, conditional morphological operators are applied to the mask, using a structural element of $3 \times 3 \times 3$ voxels. The conditional morphological operators employ thresholds computed using the statistical gray level model built in the rough-segmentation (Section 2.1.3) and gray level estimates in the neighborhood of the voxel. First, a conditional erosion is performed two times. This operation applies erosion only if the gray value in the original image is below a threshold. The threshold is the same employed in the mesh deformation, thus the voxels with gray levels in the original image $i < \mu_{\text{wm}} - 8\sigma_{\text{wm}}$ can be eroded in the binary mask. This erosion removes voxels of CSF that were misclassified as brain. Then, a conditional dilation is performed one time in the binary mask using the same structural element. The conditional dilation is applied only if the gray value in the original image is above a threshold. The threshold is determined using the maximum gray level in the original image of the voxels inside the structural element: $I_{\text{wm}}^{\text{max}}$. The value of $I_{\text{wm}}^{\text{max}}$ is an estimate of the gray level value of the brain parenchyma in the neighborhood of the voxel. If the voxel is far from the parenchyma (e.g., in a sulcus) the threshold of the conditional erosion is used. Then, the voxel may be dilated if its gray level is $i > \max(I_{\text{wm}}^{\text{max}} - 5\sigma_{\text{wm}}, \mu_{\text{wm}} - 8\sigma_{\text{wm}})$. This dilation recovers misclassified voxels of brain tissue. Fig. 11 shows the correction performed in the binary mask.

3. Databases and experiments

For the purpose of measuring the performance of our proposed SMHASS method, we use the most commonly used MRI databases:

- 20 simulated T1W MRI images from the BrainWeb website (Cocosco et al., 1997; Aubert-Broche et al., 2006), with 1 mm isotropic voxel size. This database has the ground truth segmentations for 12 tissues available, including GM, WM and CSF.
- 18 real T1W MRI images from the Internet Brain Segmentation Repository (IBSR) (Center for Morphometric Analysis, 1995), slice thickness 1.5 mm. This database has a manual segmentation of the GM, WM and CSF available.
- 40 real T1W MRI images from the Segmentation Validation Engine (SVE) (Shattuck et al., 2009) website, with 1.5 mm slice thickness and in-plane voxel resolution of 0.86 mm (38 subjects) or 0.78 mm (2 subjects). There are no ground truth segmentations available for this data set. However, segmentation masks can be sent to the website for performing an online comparison with manually edited brain mask volumes.

Our SMHASS method was validated by comparing its performance with that of three of the best methods in the literature. These methods are as follows.

The Brain Extraction Tool (BET) (Smith, 2002) that segments the brain using deformable models. The image is binarized using...
estimations of the minimum and maximum intensities of the brain. Next, the center of the head is estimated in the binarized image and the deformable model is initialized with a sphere shape in this position. The model is deformed using locally adaptive forces. BET v2.1 is free and available in the FMRIB FSL software library (FMRIB, 2012; Jenkinson et al., in press). The recommended default parameters were used for the evaluation: fractional intensity threshold = 0.5, threshold gradient = 0.

The Brain Surface Extractor (BSE) method (Shattuck et al., 2001) uses Marr–Hildreth edge detection to identify the border of the brain. Before applying the edge detector, anisotropic diffusion filtering (Perona and Malik, 1990) is used to de-noise the image. This spatially adaptive filter smooths noisy regions while preserving edge boundaries. After applying the edge detection, the image is binarized using the computed edges, and the brain is found using morphological operators. Binary erosion is applied to separate the elements and a 3D connected component analysis is carried out to identify the brain. Next, a morphological dilation is applied to the selected element (brain) to undo the effects of the erosion, and a closing operation is performed to close the small holes that may be in the volume. BSE is freely available as part of the BrainSuit (BrainSuite, 2012) of the Laboratory of Neuro Imaging (LONI) at UCLA. Two sets of parameters were used in our evaluations: the default parameters (diffusion iterations = 3, diffusion constant = 25, edge constant = 0.64, erosion size = 1), and the parameters suggested by Hartley et al. (Hartley et al., 2006; Sadanandhan et al., 2010) (diffusion iterations = 3, diffusion constant = 35, edge constant = 0.62, erosion size = 2).

The Hybrid Watershed Algorithm (HWA) (Ségonne et al., 2004) is a hybrid method that combines a watershed algorithm (Hahn and Peitgen, 2000), and a deformable surface model (Dale et al., 1999) which includes shape restrictions based on an atlas. First, a watershed algorithm that uses the concept of pre-flooding (the connectivity path between two points can contain a lower intensity than the darker of the two points up to a maximum difference) is used to segment the brain. Then, the deformable model is initialized with a balloon shape using this segmentation. A first deformation of the model is carried out using the watershed segmentation and global parameter estimations. Next, an atlas is used to verify the resulting surface and correct it if there are errors. Finally, a deformation using estimations of local parameters is performed to find the brain borders. HWA v5 is included in the FreeSurfer software package (FreeSurfer, 2012) developed at the Martinos Center for Biomedical Imaging. The default parameters and the “-atlas” option to use basic atlas information to correct the result of the deformations, were used in our tests. The default parameters are: weight for the atlas = 0.85; probability of merging = 0.32; pre-flooding height = 10; seed points using atlas information; template deforming using atlas information; use of pre-weighting for the template deformation.

To assess the improvement of our segmentation by the deformable models a comparison between the results of the rough-segmentation and the refined segmentation was also performed. The parameters used to segment the three databases with our SMHASS method were determined according to the performance over a set of training images from the three databases. Also some parameters were determined according to anatomical proportions, and expressed in millimeters. In the first deformation, l must be large enough to find the edge of the rough-segmentation if the mesh is located far away after the geometric adjustment. Besides, l must be large enough to reach the WM in the second and third deformation, but in these steps the mesh lies very close to the WM or inside it. The distance dmean must be short enough to take a measurement in the vicinity of the mesh, but large enough to diminish the effect of noise sample. Distance dmax must be large enough to reach the region behind the eyes if the mesh is in its vicinity in the WM, and short enough to avoid reaching the scalp if the mesh is in the subarachnoid space near the GM. The parameters for the first mesh deformation using deformable models were: \( \lambda = 0.4, \nu = 0.15, \gamma = 0.65, \delta = 0.5, l = 15 \text{mm} \) and \( d_l = 10 \text{mm} \). The parameters for the second and third mesh deformations were: \( \lambda = 0.4, \nu = 0.4, \gamma = 0.3, S = 2, \delta = 0.5, l = 6 \text{mm} \), \( d_{\text{min}} = 4 \text{mm} \), \( D = 0.3, d_{\text{max}} = 5 \text{mm} \), \( d_{\text{mean}} = 2 \text{mm} \), \( d_l = 0.5 \text{mm} \) and \( D_l = 1 \text{mm} \).

The two volumetric measures most used in the literature to compare the quality of skull stripping methods were employed: the Jaccard similarity (Jaccard, 1912) and the Dice coefficient (Dice, 1945). These volumetric measures can be computed using the concepts of true positive (TP), false positive (FP), true negative (TN) and false negative (FN). In our case the TP and FP are defined as the number of voxels correctly and incorrectly classified as brain tissue, respectively. Similarly, TN and FN are defined as the number of voxels correctly and incorrectly classified as non-brain tissue, respectively. The Jaccard similarity, also termed the Tanimoto coefficient, measures the similarity of two sets, \( S_1, S_2 \), as the ratio of twice the size of their intersection divided by the sum of their sizes:

\[
J(S_1, S_2) = \frac{|S_1 \cap S_2|}{|S_1 \cup S_2|} = \frac{TP}{TP + FP + FN} \tag{29}
\]

The Jaccard coefficient measures the similarity of two sets, \( S_1, S_2 \), as the ratio of twice the size of their intersection divided by the sum of their sizes:

\[
\kappa(S_1, S_2) = \frac{2|S_1 \cap S_2|}{|S_1| + |S_2|} = \frac{2TP}{2TP + FP + FN} \tag{30}
\]

The Dice coefficient is related to the Jaccard similarity by:

\[
\kappa = \frac{2J}{J + 1} \tag{31}
\]

The sensitivity and specificity percentages were also computed, which show the percentage of brain and non-brain voxels recognized respectively:

\[
\text{Sensitivity} = \frac{TP}{TP + FN}, \quad \text{Specificity} = \frac{TN}{TN + FP} \tag{32}
\]

4. Results

In the BrainWeb and IBSR databases, the ground truth was the union of GM and WM using the available segmentations. Tables 1 and 2 show the performance of the different segmentation methods using the BrainWeb and IBSR databases, respectively. In the SVE database, the ground truth is not available, but the segmentation can be evaluated by an independent online assessment that provides all used volumetric measurements. Additionally, the performance of the other methods is available online for this database. Table 3 shows the performance of the methods in the SVE database. In addition to the segmentations using the methods default parameters, segmentation performances with different parameters can be found on the SVE website. The segmentation results with better performance for each method are also shown in Table 3 marked with an *. Figs. 12 and 13 show a comparison among different segmentations of a IBSR and BrainWeb image, respectively. Fig. 13 also includes an image of the ground truth segmentation, and a zoom of the cortex for better comparison. The HWA has a low specificity in both databases (see Tables 2 and 3), nevertheless, the specificity of BSE is lower in the IBSR database when the default parameters are used (Fig. 12(d)). Also, the specificity of BET is low in the BrainWeb database (Fig. 13(d)) obtaining a low overall performance even though its sensitivity is good. The best performance was obtained by our SMHASS method (Figs. 12(f) and 13(g)), followed by BSE in
Table 1
Performance comparison among different methods using the BrainWeb database (Cocosco et al., 1997; Aubert-Broche et al., 2006). The best results are shown in bold.

Nevertheless, it has the worst overall performance (Jaccard and Dice in Table 3). The best performance is obtained by our SMHASS method (Figs. 14(d) and 15(d)).
Fig. 12. Comparison among different automatic segmentations of an image from the IBSR database (a). The BSE method has the lowest specificity when the default parameters are used (d). The HWA (b) also has a low specificity but its sensitivity is better, obtaining better overall performance. Although the performance of BSE rises considerably when Hartley’s parameters are used (e), it does not exceed the BET performance (c). Nevertheless, our SMHASS method (f) has better performance than BET.

which obtains better overall results than our SMHASS in the IBSR database: Jaccard index ($J$) = 0.915 and Dice coefficient ($\kappa$) = 0.955. Besides, its false negative rate (FNR = FN/(TP + FN + FP)) is 0.0620 and false positive rate (FPR = FP/(TP + FN + FP)) is 0.0229. The FNR and FPR of our method in the IBSR is 0.0079 and 0.087, respectively. Therefore, this method has more FN and less FP than our SMHASS. The above mentioned difference in the indices could be relativized to some extent because, as stated by many authors, it is more important to preserve the brain tissue instead of removing part of the CSF. Another method that also uses the IBSR database is the graph cuts skull stripping (GCUT) presented in Sadananthan et al. (2010), which obtains: $J$ = 0.84 and $\kappa$ = 0.91. The Robust Learning-Based Brain Extraction (ROBEX) system introduced in Iglesias et al. (2011) is evaluated using the SVE. The indices obtained by ROBEX are: $\kappa$ = 96.6, Sensitivity = 95.6, Specificity = 97.7. Another method evaluated in the SVE database is the brain extraction based on nonlocal segmentation technique (BeaST) (Eskildsen et al., 2012), obtaining $\kappa$ = 0.9781. The performance of this method is better than that of SMHASS. Nevertheless an advantage of our method is that no templates are required. The multi-atlas propagation and segmentation (MAPS) technique (Leung et al., 2011) is also evaluated in the SVE database, obtaining $J$ = 0.955. The performance of the above mentioned method is also better than that of SMHASS, nevertheless requires a template library and a long computational time (19 h). Compared to the above mentioned methods, SMHASS provides an accurate segmentation without removing brain tissue. On the other hand, the methods with a higher performance than SMHASS, such as BeaST and MAPS, are based on comparisons with template libraries and require a large amount of computation, and obviously need suitable templates for the segmentation. Besides, our method is mainly based on deformable models and only uses a simple comparison with an atlas in the rough-segmentation. Although the execution time is high in the current implementation (Python), it should drop dramatically by implementing the method in another language, which will make it faster than the aforementioned methods. There are other methods published with results on non-public databases which can not be compared. Moreover, some authors use different performance measures such as Haussdorff
Fig. 13. Comparison among different automatic segmentations of an image of the BrainWeb database (b). (a) Shows the ground truth segmentation with a marked zoom rectangular area. It can be seen that the HWA (c) is the method that leaves more non-brain tissue, mainly CSF. For this reason the HWA has the lowest specificity among the methods. The HWA has the highest sensitivity, because most of the brain tissue is included in the segmentation. Nevertheless, its overall performance (Jaccard and Dice) is lower than that of the other methods. The best performance was obtained by our SMHASS method (g), which also has the highest specificity, followed by the BSE using Hartley’s parameters.

Table 4 shows a comparison between the performance of the rough-segmentation used as initialization of our method, and that obtained at the end of the refined segmentation by deformable models. The largest improvement was achieved in the IBSR database with an increase of over 10% in the Jaccard and Dice index, followed by the improvement in the SVE database. The increase of the sensitivity index in comparison to that of the specificity shows that the improvement is mainly because the reduction of false negatives (FN). The high amount of FN (low sensitivity) in the rough-segmentation is because it is designed to remove most non-brain tissue, even if part of the brain tissue is also removed. The remotion of non-brain tissue provides an optimal starting point for the segmentation by deformable models. Besides, the removed brain tissue is recovered in the segmentation by deformable
models. These two steps are used in our method because our segmentation by deformable models has a high performance but requires a good initialization; and the rough-segmentation provides a good starting point to the deformable model.

The computational time of SMHASS for an image was about 57 min. Some of the best new methods have reported hours in computational time (Leung et al., 2011). Nonetheless, our implementation was carried out in an interpreted language (Python) that is slow but suitable for fast prototype development. We performed a simple test of gray level comparisons and computations between pixels, similar to those used in our method, to compare the computational time in Python and C++. The results of the aforementioned test show that the computational time can be reduced about 300 times if the implementation is in C++ instead of Python. Therefore, we estimate that the computational time can be reduced to less than a minute with just migrating the code to C++. We are currently working on the new implementation in C++. Moreover, the current implementation runs as a single thread but can be parallelized to take advantage of the nowadays common multi-core CPUs. Even the GPU (De Fontes et al., 2010; Courtecuisse et al., 2010) can be used to drastically decrease the computational time.

5. Conclusions

Skull stripping methods are designed to eliminate non-brain tissue in magnetic resonance (MR) brain images. This is a fundamental step for enabling processing of brain MR images. The aim of this study was to develop a new skull stripping method based on two steps: the first one a rough-segmentation that employs thresholds and morphological operators; and the second step a segmentation based on deformable models. The rough-segmentation is built on previous work but incorporates new estimations of the optimal thresholds, based on comparisons with a brain atlas. This rough-segmentation makes it possible to find an optimal initialization for the deformable model, providing robustness to the segmentation. The deformable model is based on a simplex mesh, and its deformation is guided by local image gray levels, and a gray level statistical model constructed on the rough-segmentation. The deformation is based on 3 steps which make it possible to use the rough-segmentation to find the optimal starting point for the deformation; to recover brain tissue ignored in the rough-segmentation.
and; to decrease the amount of CSF and sub-arachnoid space in the segmentation. The result of these steps is an accurate segmentation that minimizes the amount of non-brain tissue, without losing brain parenchyma.

Our Simplex Mesh and Histogram Analysis Skull Stripping, SMHASS, method was tested using international MRI databases available on the web: the BrainWeb, the Internet Brain Segmentation Repository (IBSR), and the Segmentation Validation Engine (SVE). We compared our method’s performance to that of three of the most popular methods in the literature: the Brain Extraction Tool (BET), the Brain Surface Extractor (BSE), and the Hybrid Watershed Algorithm (HWA). Performance was measured using the Jaccard index (J) and Dice coefficient (κ). Our method achieved the best performance and the difference was statistically significant (p < 0.05): J = 0.904 and κ = 0.950, on BrainWeb; J = 0.905 and κ = 0.950 on IBSR; J = 0.946 and κ = 0.972 on SVE. The obtained segmentations were accurate along all databases, and the performance variance was low. Incorporating this skull stripping method in a future method to segment the whole brain anatomy is an expectation for future work.
