The coexistence of coherent and incoherent domains in discrete coupled oscillators, chimera state, has been attracted the attention of the scientific community. Here we investigate the macroscopic dynamics of the continuous counterpart of this phenomenon. Based on a prototype model of pattern formation, we study a family of localized states. These localized solutions can be characterized by their sizes, and positions, and Yorke-Kaplan dimension. Chimera states in continuous media correspond to chaotic localized states. As a function of parameters and their size, the position of these chimera states can be bounded or unbounded. This allows us to classify these solutions as wandering or confined walk. The wandering walk is characterized by a chaotic motion with a truncated Gaussian distribution in its displacement as well as memory effects.

Localized structures are a characteristic feature of the self-organized non-equilibrium systems \cite{1,2,3}. These structures, described as particle-like solutions, are characterized by continuous order parameters like the position, width, and amplitude \cite{4}. Notwithstanding, localized structures corresponds to extended solutions. They have been observed in numerous fields, ranging from physics, chemistry to biology \cite{4,5,6}. The localized structures are the dissipative counterpart of the solitons in conservative systems. In one-dimensional systems, they can be interpreted as spatial trajectories that connect one steady state with itself. Indeed, they are homoclinic orbits of the spatial co-moving system \cite{7}. Localized structures are not necessarily motionless. As a result of symmetry breaking instabilities, they can exhibit motion or self-pulsation \cite{8,9,10,11,12,13,14}. Recently, it has been shown that parity symmetry breaking induces spontaneous motion of localized structures \cite{15}. A unified description of localized structures and their dynamic behavior can be achieved by the nonvariational Swift-Hohenberg equation \cite{16,17,18}. This model accounts for a scalar field that does not follow minimization principles. The nonvariational Swift-Hohenberg equation has been derived in several contexts \cite{19}. Moreover, this equation is used to puts light on the existence, stability properties, and dynamical evolution of complex spatiotemporal localized structures called chaoticons \cite{20}. This intriguing phenomenon is observed in a liquid crystal light valve experiment with optical feedback. Furthermore, numerically chaoticons are obtained in nonlocal nonlinear Schrödinger equation \cite{21}, Ginzburg-Landau equation \cite{22} and a reaction-diffusion model \cite{23}. Indeed, these states show a coexistence between coherence (stationary) and incoherence (spatiotemporal chaotic) domains. Hence, chaoticons are the continuous counterpart of chimera states \cite{24}, namely, chaoticons correspond to chimera-like solutions. Originally, chimera states were observed in nonlocally coupled phase oscillators \cite{25}. These intriguing states correspond to breaking symmetry solution without bistability. Extension of chimera states in bistable systems was proposed in several coupled systems \cite{26,27,28,29,30,31}, which was usually denominated chimera-like states. Depending on the initial condition, these states have different size and exhibit a family of solutions with the coexistence of coherent and incoherent domains.

Since then, chimera states have been investigated in more general frameworks \cite{32,33,34,35}. Initially, even though the existence of chimera states was attributed to the nonlocal nature of the coupling \cite{24}. Subsequently, chimera states have been observed in systems that are coupled globally \cite{36,37}, and locally \cite{26,28,39,40,41}. In all these studies, domains remain motionless. However, under special conditions, chimera states are traveling solutions. This is observed under symmetric \cite{41,42} and asymmetric schemes of coupling \cite{29,34,35}. Even, chimera states show an erratic motion with stochastic nature in a finite number of coupled oscillators \cite{43,44}. This fact is reflected by the loss of memory of the chimera position, which is counterintuitive for a deterministic system. Henceforth in this manuscript, we will use the term...
chimera to refer a complex spatiotemporal localized state in continuous media.

Unexpectedly, in a liquid crystal light valve experiment with optical feedback, an erratic walk dynamics of chaoticons is observed (see Fig. 1). This complex walk accounts for an erratic motion of the position of the complex localized structure. This dynamic is of deterministic nature. Theoretically, the chaoticon was described by the non-variational Swift-Hohenberg equation [20]. However, the reported dynamics of chaoticons of this model are characterized by erratic localized fluctuations in a bounded region of the order of one wavelength of the spatiotemporal chaotic state [20], at variance to the experimental observations characterized by an unbounded erratic walk. The mechanism that produces these states and their dynamics is an open problem.

In this paper, we investigate the erratic walk of chimera states in continuous media. Based on a prototype model of localized structures—the non-variational Swift-Hohenberg equation—we numerically observe and analyze wandering walks of localized structures. To characterize this wandering motion, we use tools of the dynamical systems and statistics theory. Finally, in comparison to the random dynamics of chimera states in coupled oscillators [46], the motion of the wandering walk of chimera-like state shows memory effects. Namely, the self-correlation of the position of this localized state does not become zero.

An archetypal model that shows patterns, fronts, localized structures, and chimera-like states in continuous media is the non-variational Swift-Hohenberg equation [19,20,47,48]. It describes the dynamics near a Lifshitz critical point [2] that accounts for the confluence of a spatial instability and a nascent of bistability through the scalar order parameter $u(x,t)$,

$$\partial_t u = \eta + \mu u - u^3 - v \partial_x u - \partial_x \partial_t u + c (\partial_x u)^2 + 2bu \partial_x^2 u,$$  \hspace{1cm} (1)

where $x$ and $t$ stand for the spatial and temporal coordinates, respectively. $\mu$ is the bifurcation parameter ($\mu < 1$), $\eta$ accounts for the asymmetry between homogeneous states, $c$, $v$, and $b$ are, respectively, the nonlinear advection, the linear and the nonlinear diffusion coefficients. The term proportional to the four spatial derivative accounts for the hyperdiffusion. Higher-order terms in Eq. (1) are ruled out by scaling analysis, since $u - \mu^{1/2}$, $\eta - \mu^{3/2}$, $v - \mu^{1/2}$, $\partial_t \mu$, $\partial_x \mu$, $\partial_x \eta - \mu^{1/4}$, and $c - b - O(1)$.

When $b = c = \eta = 0$, Eq. (1) corresponds to the well-known Swift-Hohenberg model [2,49]. The minimization of free energy characterizes the dynamics of Eq. (1). Hence, the Swift-Hohenberg equation shown only stationary solutions as equilibria. Indeed, this dynamics is of variational nature. However, in the case that $b \neq c$, model Eq. (1) loses its variational structure, allowing the existence of solutions that show permanent dynamics, such as propagative fronts [50], moving and oscillatory localized structures [15,48,51], and chimera-like states [20]. Fig. 2(a) displays a typical chimera state of model Eq. (1). This dynamic behavior is characterized by presenting localized spatiotemporal chaos, which is surrounded by homogeneous states on its flanks. It is noteworthy to note that despite its spatiotemporal complexity, the evolution of the chimera state position is localized in space, that is, the localized state is confined. To characterize the dynamics of the chimera state, let us introduce its position or centroid as

$$x_c(t) = \frac{\int L x u(x,t)dx}{\int L u(x,t)dx},$$  \hspace{1cm} (2)

where $\delta(x,t) = u(x,t) + h$ and $h$ is the distance of the homogeneous state to zero. Moreover, we consider displacements of chimera state $\Delta x_c$, taking the difference of its position between two successive time steps.

Fig. 2 shows the temporal evolution of the centroid and displacements of the chimera state. These dynamics reveal a rich and complex evolution. Note that the dynamics of the centroid is bounded by one wavelength. Hence, the chimera state remains around a given position. The statistical characterization of the centroid and displacements dynamics are shown in Fig. 2(f) and (g), respectively. In both cases, the distributions are bounded, reflecting the fact that the spatiotemporal chaotic localized structure is pinned. The richness and complexity of such kind chaotic localized structures have been studied previously in Verschueren et al. [20]. The reconstruction of the attractor for the centroid of chimera state—following the classical Fraser and Swinney method [53]—obtaining by unfolding in a 2D space is shown in Fig. 2(h). Unexpectedly, when changing parameters, the position of the chimera exhibits complex behaviors, which causes the chimera to move distances greater than the characteristic wavelength of the spatiotemporal chaotic state (cf. right panels in Fig. 3).

To the best of our knowledge, the complex and unbounded dynamical behavior of the position of chimera states has not been reported in continuous media. To investigate such localized structures dynamics, we have conducted a numerical analysis of model Eq. (1) in the nonvariational regime. For the sake of simplicity, periodic boundary conditions have been considered, however, similar dynamic behaviors are observed with other boundary conditions. Fourth-order Runge-Kutta in time and finite differences in space
are the numerical methods used to integrate model Eq. (1). In all simulations, the space is discretized in 400 points with \( dx = 0.4 \), and the time step size is \( dt = 0.001 \). Fig. 3 shows typical localized solutions exhibited by the model Eq. (1). The system shows only these three types of single localized states in a given region of parameters. These localized solutions as a function of their width are characterized by being stationary, oscillatory, or chaotic, respectively. Other localized states are a composition of their simple solutions. The top panels in Fig. 3 show profiles of each localized structure at a given time, and the bottom panels display the respective spatiotemporal evolution of localized states. Solutions that have two and three bumps correspond to stationary states, depicted in Fig. 3(d) and (e). However, a complex spatiotemporal evolution is shown by the localized structure that exhibits four bumps, see Fig. 3(f). In the former case, the system shows coexistence between coherent and incoherent domains. Indeed, this state corresponds to a chimera state, but instead of the chimera state shown in Fig. 2, it exhibits a wandering walk in its position, which is characterized by move several times the characteristic wavelength of the chaotic domain. Hence, the incoherence domain presents wandering movements which resemble a random walk [52].

Fig. 4 illustrates the temporal evolution of the four-bumps chimera solution and its respective centroid \( x_c(t) \). To figure out the sensitivity of the initial conditions on the motion of this chimera state the position \( x_c(t) \) is calculated for slightly different initial conditions [see Fig. 4(c)]. From this figure, one can infer that the position of the chimera solution presents complex dynamics as a function of the initial conditions. Likewise, to reveal the nature of the movements, we compute its displacements, taking the difference of its position between two successive time steps. Hence, the displacements are defined by \( \Delta x(t) = x_c(t) - x_c(t-\tau) \). Fig. 5 shows the temporal evolution of the displacement \( \Delta x(t) \) and its respective histogram which has a bell shape. Building the associated distribution of displacements, we found that a Gaussian distribution well describes it. Consider a fitting distribution function of the form

\[
f(\Delta x) = \frac{1}{\beta \sqrt{2\pi}} e^{-\frac{1}{2} \left( \frac{\Delta x - \mu}{\beta} \right)^2},
\]

where \( \mu \) corresponds to the mean value of the displacements \( \langle \mu \rangle = \langle \Delta x \rangle \), where the symbol \( \langle \cdot \rangle \) accounts for the average on the values of the displacements). \( \beta \) accounts for the standard deviation. The probability density distribution, and the Gaussian func-

(1) by \( \eta = -0.04, \mu = -0.09, \nu = 1, b = -2, c = 24, dx = 0.4 \) and \( dt = 0.001 \). (a) Excerpts of Spatiotemporal diagram of a wandering chimera state. (b) Temporal evolution of the centroid \( x_c(t) \) of the chimera state, calculated using formula (2), of the respective spatiotemporal evolution presented in panel (a). (c) Several trajectories of the centroid of chimera state calculated for different slightly initial conditions.

![Fig. 5](image-url) (color online) Statistical characterization of displacements of the position of the chimera solution \( \Delta x(t) \) for Eq. (1) with \( \eta = -0.04, \mu = -0.09, \nu = 1, b = -2, c = 24, dx = 0.4 \) and \( dt = 0.001 \). (a) Longtime evolution of the displacements \( \Delta x(t) \). (b) The probability distribution of displacements, which shows a Gaussian-like distribution. The continuous curve (red) accounts for a Gaussian adjustment function, formula (3), with \( \mu = 0 \) and \( \beta = 2.158 \times 10^{-3} \). The left inset shows the probability distribution of displacements in the log-log scale. This illustrates that the distribution corresponds to a truncated Gaussian. The right inset shows amplification of the tails of the distribution. (c) Self-correlation function \( R(T) \) based on Pearson’s coefficient. The fact that this function does not decay to zero highlight the memory effects of the wandering motion of chimera states. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
tion (3) are compared in Fig. 5(b). The probability distribution of displacements of chimera-like states resembles to the probability distribution of displacements of a Brownian motion. The rhythms of the displacements of a Brownian particle are completely determined by a random process [52]. However, unlike a Brownian motion, the self-correlation function \( R(T) = \langle \Delta x(t) \Delta x(t + T) \rangle \) does not decrease despite the increasing of \( T \), highlighting the memory effects of this motion. Moreover, the self-correlation shows an oscillatory behavior between a considerable maxima and minima values [see Fig. 5(c)]. Observe that \( R(T) \) was measured using the Pearson correlation coefficient. Besides, we have plotted the distribution of displacement in the log-log scale, see insets in Fig. 5(b). This chart reveals that the displacement distribution corresponds to a truncated Gaussian distribution. This type of distribution is a consequence of the central limit theorem for a finite number of elements [54–56]. To check out this result, we have conducted different numerical simulations with very long periods and of different sizes and the distribution obtained is the same.

To characterize the statistical evolution of the displacement \( \Delta x \) in a given waiting time \( \tau \), we have monitored the evolution of the displacement distribution, the standard deviation \( \sigma \), and the excess kurtosis \( \kappa \). Fig. 6 summarizes this statistical analysis. Note that \( \sigma \) and \( \kappa \) show a linear and parabolic waiting time dependence, respectively. Similar dynamical behaviour of \( \sigma \) was reported in phase coupled oscillators [46]. This type of dynamical statistical behavior is not peculiar of Brownian motion.

In brief, the position of the chimera-like state shows a wandering motion with a truncated Gaussian distribution of its displacement and memory effects.

To shed light on the dynamic nature of the wandering walk of chimera-like states, we will use tools from the theory of dynamical systems such as the power spectrum and Lyapunov exponents. These type of tools allows us to characterize the dynamics of modes and establish if the dynamics are of chaotic nature. When the largest Lyapunov exponent \( \lambda_{\text{max}} \) is negative, the system has a stationary equilibrium, for instance, homogeneous or pattern states. On the contrary, when it is positive, the system under study exhibits chaotic dynamics. Indeed, the Lyapunov spectrum characterizes the exponential sensibility to the initial conditions [57]. The analytical study of the Lyapunov spectrum is a titanic endeavor and in practice inaccessible. The numerical derivation of the exponents is a standard strategy. Indeed, it is necessary to spatially discretize the model Eq. (1). Hence, model (1) is approximated to a set of coupled ordinary differential equations, discretized system. From these equations, one can determine the discretized Jacobian at the chaotic solution, which characterizes the linear evolution of the state under study. To determine the Lyapunov exponents, we follow the linear evolution of an orthonormal deviation vectors basis of the discretized system. At every temporal evolution step, the deviation vectors are replaced by a new set of orthonormal vectors. From these orthonormalization procedures, Lyapunov exponents are estimated (see Ref. [58] for more details). We have calculated numerically the leading Lyapunov exponents of the chimera solution. Fig. 7 shows the positive Lyapunov spectrum of the chimera solution. From this spectrum, it is inferred that the strange attractor has at least 4 unstable directions. Note that few exponents are positive, which highlight a low-dimensional chaotic dynamics. In addition, one can determine the dimension of the strange attractor that characterizes the dynamics of the position of the chimera-like solution, using the Yorke-Kaplan conjecture [59]. The Yorke-Kaplan dimension is defined as \( D_K = n + \sum_{i=1}^{n} \lambda_{i+1}/|\lambda_{i+1}| \), where \( n \) is the largest integer such that \( \lambda_{i+1} + \lambda_{n} > 0 \). Fig. 7(a) shows the partial sum of the Lyapunov exponents \( \Gamma_i = \sum_{k=1}^{i} \lambda_k \). From this chart, we found that \( n = 10 \). Then, the dimension is \( D_K \approx 10.005 \). Besides, Fig. 7(b) displays the power spectrum of the temporal evolution of the displacements. The complex evolution of the wandering chimera state is revealed in a large number of frequency that is involved in the dynamics, which is typical of chaotic behaviors.

\end{figure}
Therefore, from the previous analysis, we infer that the wandering walk of the chimera-like solution is of a chaotic nature. The wandering chimera-like states are observed in a wide range of parameters, which is a manifestation of the robust nature of these localized states. Fig. 8 shows the phase diagram of chimeras with wandering walks in \( \eta - c \) parameters space. Hence, chimeras with wandering walks are observed in a wide region of the parameter space. It is important to note that these chimeras with wandering walks can coexist with motionless localized structures and confined chimeras.

In conclusion, we have shown that wandering dynamics of the position of chimera solutions in continuous spatially extended systems. These intriguing states are observed in the nonvariational Swift-Hohenberg equation, which is a prototype model of pattern formation. We have investigated the statistical and dynamical properties of wandering chimeras. The wandering walk of these solutions shows a truncated Gaussian distribution in its displacements. This property and the sensitivity to the initial conditions resemble a sort of Brownian motion. However, the wandering walk of the chimera states exhibits memory effects that are characterized by the self-correlation function. Besides, we have shown that the evolution of the position of wandering chimera-like state corresponds to chaotic behavior. To support this statement, the leading Lyapunov exponents were calculated.

Due to the generic character of the nonvariational Swift-Hohenberg equation, we expect the observation of wandering chimera-like states in a wide range of systems. In addition, we can take advantage of these wandering chimera-like states as Brownian motors [60] to induce propagation or control of coexisting localized structures. Finally, this work provides insights into novel ways of light beam generation with coexisting coherent and incoherent domains. The incoherent domain remains in a wandering motion. We expect that such kind of light beam will have significant and far-reaching ramifications in the development of novel and practical technological applications. Work in this direction is in progress.
